Accommodation of genotype-environment covariance in a longitudinal twin design

In the classical twin study, genetic and environmental influences on a phenotype are usually estimated under the assumption that genotype-environment covariance (GE covariance) is absent. We explore possibilities to accommodate GE covariance in longitudinal data using the genetic simplex model. First, the genetic simplex model is presented, accompanied by a brief summary of results found in cognitive developmental studies. Second, GE covariance is specified via niche picking and sibling effects. Third, numerical and analytical identification is established, and the statistical power to detect GE covariance is examined. In a simplex model comprising four time points, GE covariance can be accommodated by introducing phenotype to environment cross-lagged pathways, either within or between twins. By using different parameter constraints within the genetic simplex, the extended models are numerically and analytically identified. The power to detect GE covariance is relatively low and therefore large sample sizes are needed.

Most applications of the classical twin design come with well-known model assumptions, including absence of genotype by environment interaction (GxE interaction), zero genotype-environment covariance (GE covariance) (see dotted arrows in Figure 1), and random mating (i.e., zero spousal correlation; Eaves et al., 1977). These assumptions are known, or are suspected, to be violated to some degree in different complex traits. For instance, it is well known that assortative mating plays a role in intelligence (i.e., a positive correlation between IQ test scores of spouses; Eaves, 1973). For example, if data on parents of twins are available this information can be accommodated in the twin model (e.g., Martin, Eaves, Heath, Jardine, Feingoldt, & Eysenck, 1986). GxE interaction, i.e., moderation of genetic effects by environmental variables, or a dependence of environmental exposures on genotype, has been assessed thanks to advances in statistical modelling, enabling researchers to incorporate measured moderators, such as SES, into the twin model (Purcell, 2002; Harden, Turkheimer, & Loehlin, 2006; Boomsma & Martin, 2002). GE covariance has generally received less attention, although theoretically GE covariance is probably important, and has been hypothesised to explain increased heritability with age (Kan, Wicherts, Dolan, & Van der Maas, under revision).

The absence of GE covariance is certainly a strong assumption for many complex traits (Plomin et al., 2008). This assumption is often made pragmatically; in a design that includes only MZ and DZ twins applied to univariate data obtained at a single occasion, the covariance between genetic and environmental influences is not identified, and therefore cannot always be estimated. Here we explore whether GE covariance can be estimated from longitudinal data in the classical twin design using the genetic simplex (Boomsma & Molenaar, 1987). The genetic simplex provides a decomposition of phenotypic variance into genetic and environmental components at each measurement occasion (Figure 2). In addition, the genetic simplex expresses the phenotypic stability, i.e., the phenotypic correlation of a trait over time, in terms of genetic and environmental stability. In the standard genetic simplex, GE covariance is assumed to be absent as there is no direct or indirect pathway between genotypic and environmental components (Figure 2).

Developmental psychologists and behaviour geneticists, however, have long recognised definite processes giving rise to GE covariance (Carey, 1986; Eaves et al., 1977; Loehlin & DeFries, 1987; Plomin, DeFries, & Loehlin, 1977; Scarr, 1992; Scarr & McCartney, 1983). An important theoretical distinction is made between passive, reactive, and active GE covariance (Loehlin & DeFries, 1987; Plomin et al., 1977; Scarr, 1992; Scarr & McCartney, 1983): passive GE covariance arises when parents supply both genes and environment during the development of their offspring (i.e., ‘smart’ parents transmit ‘smart’ genes and provide a ‘smart’ environment); reactive GE covariance arises when certain genotypes evoke certain reactions in the environment (e.g., ‘smart’ individuals evoke ‘smart’ reactions from their environment); and active GE covariance arises when individuals actively seek out environments consistent with their phenotype (i.e., ‘smart’ children seeking out a ‘smart’ environment). Provided that individual differences in the phenotype are at least partially due to genetic factors, these processes give rise to GE covariance.

Two conceptualisations of GE covariance are niche picking and sibling effects. Niche picking gives rise to within-individual GE covariance, as it involves an individual’s choice or preference for certain environments, based on personal interest, talent, and personality (Scarr, 1992, Scarr & McCartney, 1983). This process thus implies a pathway between the individual’s genotype and his or her environment, possibly mediated via the phenotype. Sibling effects give rise to between-individual GE covariance, as one sibling might directly or indirectly influence the other sibling’s environment (Eaves, 1976; Carey, 1986), creating a pathway from one individual’s genotype toward another individual’s environment.
The aim of the present paper is to consider the specification of GE covariance processes in the genetic simplex and to explore the possibility to incorporate GE covariance in longitudinal twin models. We limit ourselves to the processes of niche picking and sibling effects in the simplex model including additive genetic (A) and unique environmental effect (E), and in a special case of a model with A, E, and common environmental effects (C) (see below). The setup of this paper is as follows: First, we represent the genetic simplex model, which we use as our starting model in which we incorporate GE covariance. Second, we consider the specification of GE covariance as arising through the processes of niche picking and sibling effects in three models: the within twin member’s niche picking model, the between twin members’ sibling effects model, and the combination of these two in the combined model. Third, we investigate the identification and resolution of these extended models, and compute the power to detect the parameters which give rise to GE covariance. We conclude with a brief discussion.

The genetic simplex

The genetic simplex model (Boomsma & Molenar, 1987) has been used extensively to model longitudinal data in the classical twin design (e.g., Bartels et al., 2002; Bishop et al., 2003; Cardon et al., 1992; Petrill et al., 2004; Rietveld et al., 2000). The genetic simplex involves the regression of the phenotype measure at time point \( t \), \( P_{ij} \), on the additive genetic (\( A_{ij} \)), common (\( C_{ij} \)), and unique environmental variables (\( E_{ij} \)):

\[
P_{ij} = A_{ij} + C_{ij} + E_{ij} + e_{ij}
\]

where \( t \) denotes the measurement occasion (\( t=1...T \)), \( i \) denotes the twin pair, and \( j \) denotes the twin member. The term \( e_{ij} \) represents an occasion-specific residual, which may include genetic and environmental influences along with measurement error. Assuming the variables \( A, C, \) and \( E \) are uncorrelated, and given a correction for the occasion specific variance \( \text{var}(e) \) (e.g., if \( \text{var}(e) \) is a pure measurement error, this would be a correction for attenuation), the implied decomposition of variance at occasion \( t \) is

\[
\text{var}(P) = \text{var}(A) + \text{var}(C) + \text{var}(E),
\]

(2)

and the narrow sense heritability is \( h^2 = \text{var}(A)/[\text{var}(A)+\text{var}(C)+\text{var}(E)] \). The phenotypic stability is modelled by specifying autoregressive processes for \( A, C, \) and \( E \). Limiting the equations to the additive genetic process, this entails the regression of \( A_{ij} \) on \( A_{i,j-1} \):

\[
A_{ij} = \beta_{A_{ij}} A_{i,j-1} + \xi_{A_{ij}},
\]

(3)

where \( \beta_{A_{ij}} \) is the autoregressive coefficient and \( \xi_{A_{ij}} \) is the residual, or innovation term. The implied variance decomposition is \( \text{var}(A_{ij}) = \beta_{A_{ij}}^2 \text{var}(A) + \text{var}(\xi_{A_{ij}}) \), where \( \text{var}(\xi_{A_{ij}}) \) is the residual or innovation variance. The covariance between \( A \) at \( t \) and \( t+1 \) equals \( \text{cov}(A_{i,j},A_{i,j+1}) = \beta_{A_{ij}} \text{var}(A) \). We may also consider the percentage of explained variance in this regression, i.e., \( R^2_{A_{ij},A_{i,j+1}} = \beta_{A_{ij}}^2 \text{var}(A) \). Note that this percentage depends on the relative magnitudes of the autoregressive coefficient, \( \beta_{A_{ij}} \), and the residual variance, \( \text{var}(\xi_{A_{ij}}) \). The regression model applies to \( C_{ij} \) and \( E_{ij} \) as well, so that the phenotypic covariance of the phenotype at \( t \) and \( t+1 \) is decomposed as follows:

\[
\text{cov}(P_{i,j},P_{i,j+1}) = \beta_{A_{ij}} \text{var}(A)+\beta_{C_{ij}} \text{var}(C)+\beta_{E_{ij}} \text{var}(E).
\]

(4)

The genetic simplex provides an informative decomposition of the phenotypic variance at each occasion and of the contribution of genetic and environmental effect to the stability and change over time. Note that in the simplex (i.e., excluding the parameters giving rise to GE covariance), the first and the last occasion specific variances (\( \text{var}(e) \)) are not identified. Identification can be achieved by setting these terms to zero, or by the imposition of the constraints \( \text{var}(e_1) = \text{var}(e_T) \) and \( \text{var}(e_{T-1}) = \text{var}(e_2) \). During our model evaluation, we imposed these latter equality constraints. Also note that the model includes several special cases. For instance, if the parameters of \( \beta_2 \) approach zero this implies that genetic effects do not contribute to stability. If \( \text{var}(\xi) \) approaches zero (given \( \beta_1 \) are not equal to zero), the genetic stability is perfect (i.e., \( R^2 \) approach 1). If this is the case throughout the time period considered, the (genetic part of the) autoregressive model tends towards a single common factor model (Bishop et al., 2003).

Twin studies based on the genetic simplex have provided detailed information on the contributions of genetic and environmental factors to the longitudinal covariance structure of complex traits, such as cognitive abilities. During the development of cognitive abilities during early childhood, the influences of additive genetic components (A) follow a simplex pattern (i.e., both \( \beta_1 \) and \( \text{var}(\xi) \) greater than zero; Bishop et al., 2003; Cardon et al., 1992; Rietveld et al., 2000, Petrill et al., 2004). As such, additive genetic influences are both a source of stability and change. Unique environmental influences (E) mostly contribute to instability, as \( \beta_1 \) are relatively low and \( \text{var}(\xi) \) are non-zero (Bartels et al., 2002; Cardon et al., 1992; Petrill et al., 2004; Rietveld et al., 2000). Common environmental influences (C) mostly contribute to stability during early development, as \( \beta_1 \) tend to approach unity and \( \text{var}(\xi) \) tend to zero (Bartels et
al., 2002; Bishop et al., 2003; Cardon et al., 1992; Petrill et al., 2004; Rietveld et al., 2000). Common environmental influences decrease in magnitude later in life, disappearing altogether in late adolescence. In addition, it has been established that the relative contribution of $A$ increases, and that of $E$ decreases over time (i.e. heritability increases over time, e.g., Bartels et al., 2002; Bishop et al., 2003; Boomsma et al., 2002; Haworth et al., 2010; Petrill et al., 2004). Although the contributions of heritability and environment are robust and well established, the role of GE covariance has not been taken into account in these longitudinal studies.

Methods

Introducing GE covariance processes

We took the genetic simplex (Figure 2) as our starting model to introduce parameters giving rise to GE covariance. The simplex, as shown, accommodates common environmental influences ($C$) by the specification of correlated environmental influences (dotted arrows) rather than by the specification of a separate simplex process for $C$. By assessing the total environmental effects ($E^* = C + E$), instead of estimating each component separately, the specification and investigation of GE covariance originating in sibling effects and niche picking is greatly simplified. So we considered two different models namely; 1) the $AE$ model in which only additive genetic variance ($A$) and unique environment ($E$) influence the phenotype ($P$);

Model 1
Niche picking
$P_{t,1} \rightarrow E_{t+1,1}$
$P_{t,2} \rightarrow E_{t+1,2}$

Model 2
Sibling effects
$P_{t,1} \rightarrow E_{t+1,2}$
$P_{t,2} \rightarrow E_{t+1,1}$

Model 3
Niche picking & Sibling effects
$P_{t,1} \rightarrow E_{t+1,1}, P_{t,2} \rightarrow E_{t+1,2}$

By introducing crossed lagged phenotype to environment pathways within the two longitudinal models, we accommodated GE covariance within (i.e., niche picking) and between twins (i.e., sibling effects). Specifically, we viewed niche picking as the influence of phenotypic variable at occasion $t$ on the environmental variable at time point $t+1$ within each individual (Figure 3, Model 1). We accommodated sibling effects by introducing a cross lagged pathway from the phenotypic variable of one twin member at occasion $t$ on the environment of the other twin member at time point $t+1$ (Figure 3, Model 2).

Finally, these two models can be combined (Figure 3).

Note that our $AE^*$ simplex model is nested under the standard ACE simplex model, i.e., the standard ACE simplex will fit data generated with our $AE^*$ simplex model. The $AE^*$ simplex implies that in the standard ACE simplex the autoregressive coefficients of the E simplex equal those of the C simplex. This nesting is amenable to statistical testing.

Note that this parameterisation of sibling effects deviates from previous methods such as that of Carey (1986) in which a polynomial was used to estimate GE covariance.
Model 3), incorporating niche picking and sibling effects simultaneously. Note that we did not consider the direct path from A to E. Therefore we worked under the assumption that any effect of A on E must be mediated by the phenotype P. Still the pathway from P to E does imply GE covariance, as with this path in place, A and E are connected indirectly. For instance, in model 1 of Figure 3, the parameter between A\_t and E\_t+1,1 is due to the path from A\_t to P\_t, and from P\_t to E\_t+1,1.

Model evaluation
To establish whether extending the simplex model (i.e., the proposed cross lagged pathways) is practically feasible, we evaluated the extended models with respect to local identification, resolution, and power. First, we established model identification, which concerns the question whether the unknown parameters in the model can be estimated uniquely given appropriate longitudinal twin data. We distinguished between numerical and analytical identification. We considered both, because analytical identification does not rule out empirical under-identification. Empirical identification implies that fitting the true model to exact population MZ and DZ matrices produces a zero $\chi^2$ value and perfect recovery of the parameter estimates regardless of variation in the starting values. A model is analytically identified if the Jacobian matrix of the model is of full column rank (Bekker, Merckens, & Wansbeek, 1993). The elements in the Jacobian matrix are the derivatives of each element in the population (MZ and DZ) covariance matrices to the unknown parameters (Derks, Dolan, & Boomsma, 2006; see also Bollen & Bauldry, 2010). We established analytical identification using the Maple program (Heck, 1993). To specify GE covariance, we added the cross lagged parameters (i.e., the additional parameters in the models depicted in Figure 3) to the basic simplex, without giving any additional constraints. If this model is not identified, we proceeded by imposing constraints on the parameters underlying GE covariance or on the other parameters in the model (Maple input is available on request). Second, we determined the resolution to see how well the competing models can distinguish between different effects. It is necessary to establish that two models (say model 1 and 2, as depicted in Figure 3), while both being identified, are not equivalent (i.e., they should not fit the data containing different effects equally well). To establish this, we fitted data generated according to one model and fitted all other models, which should result in misfit expressed in $\chi^2$ values greater than zero. Third, we computed the power of each model to detect the parameters underlying the GE covariance, given an $\alpha$ of .05. To calculate the power, we first constructed MZ and DZ population covariance matrices according to the model of interest, i.e., giving the parameters underlying the GE covariance a certain value. Fitting the true model will then produce a $\chi^2$ statistic of zero. Dropping the parameter of interest, i.e., those associated with niche picking and/or sibling effects, will result in a positive $\chi^2$ statistic. This statistic can be used to calculate the power to detect the parameters underlying the GE covariance (Satorra & Saris, 1985). We computed the power for all nested models (Figure 4) using sample sizes up to 3000 twins and a fixed $\alpha$ of .05 (R scripts are available on request).

Calculation of covariance matrices
The numerical population MZ and DZ covariance matrices are calculated in four different scenarios (no GE covariance; GE covariance in the form of niche picking, GE covariance in the form of sibling effect, GE covariance in the form of a combined effect; see Figures 2 and 3), the two different models (AE and AE'), four time points and 1000 MZ and 1000 DZ twin pairs (see Table 1 for parameter values). In the AE' models, we included common environmental variance as the covariance between the environmental variables. To accommodate increasing heritability, the genetic innovations terms var($\zeta_k$) and the autoregressive coefficients $\beta_x$ increase with time, while the values for the environmental innovations terms var($\zeta_k$) and the autoregressive coefficients $\beta_x$ decrease. The strength of the niche picking effect ($\beta_{pe}$, i.e., the GE covariance due to paths from P\_t to E\_t+1,1, and from P\_t to E\_t+2,2; see Figure 3) is set to equal .1 for the first time point $t$, adding a value of .01 for each additional time point. The strength of the sibling effects ($\beta_{pe}$, i.e., GE covariance due the path from P\_t to E\_t+1, and P\_t to E\_t+2; see Figure 3) is set to .05 at time point one, again adding a value of .01 for each additional time point (* indicates these parameters concern the sibling effects). We chose the
Results

Model identification

We first established analytic identification of the three GE covariance extensions (Figure 3) in both the AE and the AE* models. To establish which constraints are identifying, we started with the most unconstraint model, a model without any equality constraints on the parameters, except for the standard equality constraints on the occasion specific variance mentioned above (i.e., var(e) = var(e), and var(e) = var(e)), and worked through different constraints to see if the models were identified (see Table 2). Note that the basic model is identified if the parameters underlying GE covariance are fixed to zero.

The analytical identification procedures indicated that none of the extended models are identified without additional constraints. This was true in both the AE and the AE* models. For each extension (i.e., either for niche picking, sibling effects, or these effects combined), we determined which restrictions rendered the models identified. To this end, we first explored the possibilities within the parameters used to model GE covariance. One way to restrict the GE covariance parameters is by constraining the GE covariance parameters to be equal over time (i.e., for niche picking model: βPEt+1 = βPEt+2 = βPEt+3, for sibling effects model: βPEt+1 = βPEt+2 = βPEt+3, and for the combined model: βPEt+1 = βPEt+2 = βPEt+3 and βPEt+1 = βPEt+2 = βPEt+3). These equality constraints resulted in identification of the models in both the AE and the AE* models. A less restrictive identifying constraint is the use of a two parameter model (i.e., βPE = δ00 + δ01(t-2), in which δ00 resembles the intercept of the regression (i.e. the initial influence of GE covariance) and δ01 the direction coefficient of the regression slope coefficient (i.e. the change in the influence of GE covariance with time). By using the two parameter model we allowed linear changes in the GE covariance estimates over time. We used the following parameters for the niche picking model: βPEt+1 = δ00 + δ01(t-2), the sibling effects model: βPEt+1 = δ00 + δ01(t-2), and for the combined model: βPEt+1 = δ00 + δ01(t-2) and βPEt+1 = δ00 + δ01(t-2). Again this identifying constraint resulted in model identification. By using different constraints for the GE covariance parameter, the extended models are thus identified.

Second, we explored constraints on other parameters in the model to determine if these constraints rendered the parameters underlying GE covariance identified (without imposing any constraints on these parameters). As can be seen in Table 2, in the sibling effects model, many different constraints render the sibling effect parameters (i.e., model 2 in Figure 3) occasion specific variance (var(e)) to approach 20% of the phenotypic variance. While the parameter values chosen here are somewhat arbitrary, the parameters do give rise to summary statistics that resemble those reported in the literature on cognitive abilities. That is, given the present parameter values, heritability increases over time (h2 = .50, .62, .679, & .774). We performed numerical analyses using R (R Development Core Team, 2012) and LISREL 8.80 (Jöreskog & Sörbom, 2006).

identified. Within the niche picking model and combined model (models 1 and 3 in Figure 3), only constraints on the autoregressive coefficients (i.e., either $\beta_A^{t+1} = \beta_A^{t+2}$ or $\beta_A^{t+1} = \beta_A^{t+2}$ or $\beta_A^{t+2} = \beta_A^{t+3}$ or $\beta_A^{t+1} = \beta_A^{t+2} = \beta_A^{t+3}$ $\beta_A^{t+1} = \beta_A^{t+2} = \beta_A^{t+3} = \beta_A^{t+4}$ rendered the GE covariance parameters identified.

Lastly, we established numerical identification for each of the three GE covariance extensions (see Figure 3) in both the AE and the AE* models using the two parameter model to estimate GE covariance. To do so, we first calculated the population MZ and DZ covariance matrices, to which we fitted the data generating model, i.e., the true model under which the covariance matrix is calculated, in LISREL 8.80 (Jöreskog & Sörbom, 2006). Although our results are limited to the parameter values chosen, we had no trouble fitting these models in LISREL. This suggests that, given the chosen parameter values, empirical under-identification was not a problem.

### Resolution of the models
To determine whether the models were distinguishable, we generated MZ and DZ covariance matrices for all different effects (no effect, niche picking effect, sibling effect, combined effect) for both AE and the AE* models, and fitted various competing models to these covariance matrices (see Table 3). For instance, we fitted the niche picking model to covariance matrices generated with the sibling effects.

Our analyses led to several noteworthy observations (Table 3). First, in both AE and AE* models, fitting the basic model (i.e., no GE covariance) to the covariance matrices including GE covariance parameter leads to deviations from the zero $\chi^2$ value. This shows the possibility to distinguish our proposed GE covariance models from the basic genetic simplex model. The low $\chi^2$ value obtained when fitting the basic model to niche picking data, indicates low power given any reasonable $\alpha$. Thus given the chosen parameters values, niche picking (i.e., within individual GE covariance) has a relatively weak effect on the phenotypic covariance structure. The higher $\chi^2$ values, obtained when fitting the basic model to the sibling effects (i.e., between twin GE covariance) and combined model, indicate greater power, and thus a stronger effect on the phenotypic covariance structure.

Second, when fitting the different GE covariance models to covariance matrices generated under the basic genetic simplex (i.e., fitting models with GE covariance parameters to data where GE covariance is absent) led to perfect model fit, as expected. This shows that the GE covariance parameters are correctly estimated to be zero when a GE covariance effect is absent. Third, when fitting the sibling effects model to niche picking or combined data, the model fit is almost perfect. This again indicates that the niche picking effect is hard to detect and to distinguish from the sibling effect. Fourth, fitting the niche picking model to the sibling effects and combined data led to large $\chi^2$ values, which indicates that when the sibling effect is present, the niche picking model will not fit well.

### Statistical power
The statistical power to detect different forms of GE covariance depends on the sample size and on $\alpha$. Table 4 and Figure 5 give an overview of the number of twins needed to attain certain power given an $\alpha$ of .05. It can be concluded that, in terms of power, detecting niche picking is more difficult than detecting sibling effects. This conclusion is in line with the results presented earlier, where we found that the $\chi^2$ values were lower when fitting the basic simplex to data including the sibling effect than to data including the sibling effects. The greatest power is found for the detection of the combined effects. It should be noted that this is an omnibus test, in which the power to detect sibling effects and niche picking effects are combined. When computing the power to detect these effects separately, it is clear that the sibling effects are easier to detect (Figure 5).

*Models that experience computational problems when certain parameter values are used to calculate the MZ and DZ covariance matrices.

The statistical power to detect different forms of GE covariance depends on the sample size and on $\alpha$. Table 4 and Figure 5 give an overview of the number of twins needed to attain certain power given an $\alpha$ of .05. It can be concluded that, in terms of power, detecting niche picking is more difficult than detecting sibling effects. This conclusion is in line with the results presented earlier, where we found that the $\chi^2$ values were lower when fitting the basic simplex to data including the sibling effect than to data including the sibling effects. The greatest power is found for the detection of the combined effects. It should be noted that this is an omnibus test, in which the power to detect sibling effects and niche picking effects are combined. When computing the power to detect these effects separately, it is clear that the sibling effects are easier to detect (Figure 5).
The aim of this paper was to specify processes giving rise to GE covariance within the genetic simplex model. To model GE covariance in the genetic simplex, we introduced phenotype to environment cross lagged relationships, representing niche picking effects, sibling effects, and the combined effects. We considered two models: one model with additive genetics and unique environmental influences (AE), and one model in which we accommodated the common environmental influences by covariance between E of each twin (AE*). First, we demonstrated the possibility to accommodate GE covariance in both the AE and AE* simplex models. The additional GE covariance parameters are identified under various identifying constraints. Identifying constraints may be imposed on the parameters accounting for the GE covariance. For instance, equality constraints and the use of a two parameter model (constraining the change in the parameters to be linear) rendered the model identified. Identification can also be achieved by imposing constraints on the standard parameters in the genetic simplex (e.g., the autoregressive coefficients). Given such constraints the parameter used to model GE covariance can be estimated freely at each time point. Second, we showed that it is possible, in principle, to determine whether an effect of GE covariance is present or not, as fitting a different model than the data generating model leads to non-zero $\chi^2$ values. Third, we showed that relatively large sample sizes are needed to reach sufficient power to detect GE covariance effects, given our present parameter values. It turns out that the power to detect GE covariance depends on the type of effect. Larger sample sizes are needed to detect the niche picking effects than the sibling effects or combined effects. As power depends on the number of observations, we expect that adding time points to the models will lead to greater power in addition to simply increasing the sample size.

We emphasise that the present study is a first step towards establishing viable twin models including processes giving rise to GE covariance. Our present results are limited in the following respect. First, our results are limited to the scenarios considered, both in terms of measurement occasions (T=4) and of our choice of parameter values in our numerical results. Increasing the number of occasions is not likely to given rise to problems of identification. However, fewer occasions (say, 2 or 3) requires further study.

Second, our results concerning power and resolution depend wholly on our choice of parameter values, and are limited accordingly. More extensive power analyses were beyond the present scope, but we
note that such analyses pose no great problem to carry out, and can be tailored to the researcher’s specific expectations. Our explorations of other parameter values showed that identification did not depend on the exact values (as expected). However, we did find that certain choices of parameters resulted in computational problems in fitting the basic (i.e., excluding parameters giving rise to GE covariance) genetic simplex. Notably, low values of the environmental autoregressive coefficient \( \beta_{E,t} = \beta_{E,t+2} = 0.15, \beta_{E,t+3} = 0.2 \) in the sibling effects and the combined model rendered the basic simplex model computationally hard to fit as the occasion specific residual variances assumed negative values. This problem can be resolved by fixing these variances to zero.

Finally, we have only considered the AE model and the AE* model. The AE model is standard in the absence of common environmental influences (C). The AE* model treats common and unique environmental influences as ‘total environmental effects’, rather than explicitly modelling separate E and C processes. The AE* model is nested under the ACE model (as the ACE model with equal autoregressive C and E parameters implies the AE* model). In our current exploration of GE covariance, we only considered processes giving rise to AE covariance or AE* covariance. We have not addressed other sources of covariance, such as AC covariance, which are distinct from AE* and AE covariance, as these forms were beyond the scope of this article. We hope to extend our present results to the ACE model in the near future.

We conclude that sibling interaction and niche picking, conceptualised as the regression of environmental influences (E or E*) on the phenotypic variable, can be accommodated in the genetic simplex models considered here. While these models are identifiable given appropriate constraints, the issue of power requires attention, as does the generalisation to the standard ACE model. The application of these models, given adequate sample sizes, will ultimately allow one to establish whether these sources of GE covariance play any role in complex phenotypes, as is often suggested (e.g., in discussions of cognitive abilities).
