Summary
The accumulation of epigenetic changes was proposed to contribute to the age-related increase in the risk of most common diseases. In this study on 230 monozygotic twin pairs (MZ pairs), aged 18–89 years, we investigated the occurrence of epigenetic changes during the adult lifespan. Using mass spectrometry, we investigated variation in global (LINE1) DNA methylation and in DNA methylation at INS, KCNQ1OT1, IGF2, GNASAS, ABCA1, LEP, and CRH, candidate loci for common diseases. Except for KCNQ1OT1, interindividual variation in locus-specific DNA methylation was larger in old individuals than in young individuals, ranging from 1.2-fold larger at ABCA1 (P = 0.010) to 1.6-fold larger at INS (P = 3.7 × 10^-07). Similarly, there was more within-MZ-pair discordance in old as compared with young MZ pairs, except for GNASAS, ranging from an 8% increase in discordance each decade at CRH (P = 8.9 × 10^-10) to a 16% increase each decade at LEP (P = 2.0 × 10^-08). Still, old MZ pairs with strikingly similar DNA methylation were also observed at these loci. After 10-year follow-up in elderly twins, the variation in DNA methylation showed a similar pattern of change as observed cross-sectionally. The age-related increase in methylation variation was generally attributable to unique environmental factors, except for CRH, for which familial factors may play a more important role. In conclusion, sustained epigenetic differences arise from early age to old age and contribute to an increasing discordance of MZ twins during aging.

Key words: epigenetics; aging; MZ twin design; full adult lifespan; DNA methylation; stochastic variation.

Introduction
The risk of most common diseases increases with age. A lifetime of accumulated epigenetic changes was proposed to contribute to the development of such diseases (Bjornsson et al., 2004). Epigenetic mechanisms determine the expression potential of genes without changing the DNA sequence (Jaenisch & Bird, 2003). The molecular basis includes the methylation of cytosines in CpG dinucleotides, which, together with histone modifications, noncoding RNAs, and localization, influence the accessibility of a genomic locus to the transcriptional machinery (Bernstein et al., 2007; Cedar & Bergman, 2009). DNA methylation can be measured on DNA samples that are commonly available in biobanks (Talens et al., 2010).

Various studies have investigated whether DNA methylation can change with increasing calendar age. A cross-sectional study of limited sample size reported the genome-wide absence of changes in mean DNA methylation between young (26 years) and old (68 years) individuals (Eckhardt et al., 2006). However, cross-sectional studies that focus on changes in mean DNA methylation can only detect age-related changes that are in the same direction for most individuals. A cross-sectional study that focussed on DNA methylation at the COX7A1 focus reported greater interindividual variation in 20 elderly individuals (> 60 years old) compared with 20 young individuals (< 30 years old; Ronn et al., 2008), indicating that DNA methylation can indeed change with age in a direction that differs per individual.

Longitudinal studies are even better suited to investigate this type of age-related methylation changes, even though most of them rarely span more than a period of two decades. A study on global DNA methylation, a measure of the average methylation level of (a representative portion of) CpG sites across the genome, observed changes with a direction that was individual specific in whole-blood samples of 111 individuals (59–86 years) followed over 11 years and 127 individuals (5–72 years) followed over 16 years (Bjornsson et al., 2008). Yet, two smaller studies with 10–20 years of follow-up demonstrated that at specific genomic loci, DNA methylation in blood and buccal swab samples can remain remarkably stable (Feinberg et al., 2010; Talens et al., 2010).

A particularly powerful design to investigate the accumulation of epigenetic changes with age is studies of monozygotic twins (Bell & Spector, 2011). MZ co-twins have the same age and a virtually identical genotype, thus controlling for their effect on DNA methylation (Heijmans et al., 2007; Bell et al., 2011), while they may differ in their lifetime exposure to environmental factors and can develop small phenotypic differences with age (Martin et al., 1997). To our knowledge, only one study has as yet adopted this design to study age-related changes into adulthood. This study on 40 MZ pairs aged 3–74 years reported that older MZ pairs (> 28 years old) showed larger within-pair epigenetic differences than younger MZ pairs (< 28 years old) in total DNA methylation and total histone acetylation levels. Although the functional relevance of such measures is uncertain, analysis on smaller subsets of MZ twins indicated similar trends at sites throughout the genome, most of which were repetitive sequences, but also included singly copy genes (Fraga et al., 2005). Also, it remains unclear at what age such changes start to arise in the population and at what rate they subsequently progress with increasing age.
The studies performed thus far were generally relatively small, focused on measures of average methylation of the genome, and/or could investigate limited periods of the adult lifespan only. Here, we report on age-related changes in locus-specific DNA methylation in a combined cross-sectional and longitudinal study on 460 individuals comprising 230 MZ pairs aged 18–89 years. The long age range investigated allowed us to study whether epigenetic changes accumulate linearly, exponentially, or in bursts during the full adult lifespan. Furthermore, we evaluated the influence of familial versus individual factors on the age-related increase in discordance. We assessed both global DNA methylation with the LINE1 assay (Wang et al., 2010) and locus-specific DNA methylation close to genes implicated in various age-related diseases, namely the nonimprinted locus LEP, ABCA1, and CRH and the imprinted loci IGF2, INS (alternate symbol INSGIF), KCNQ1OT1 (alternate symbol KVDMR), and GNASAS (alternate symbol NESPAS). These loci were selected on the basis of their previously shown features of epigenetic regulation as observed in human, animal, or cell culture experiments (Mitsuya et al., 1999; Melzner et al., 2002; Cui et al., 2003; Probst et al., 2004; McGill et al., 2006; Williamson et al., 2006; Kuroda et al., 2009; Table 1).

Results

DNA methylation in young and old MZ twins

Means and interindividual variation

Global DNA methylation and methylation status at nine specific loci were compared between young twins (n = 132 individuals) and old twins (n = 134 individuals). Old individuals had slightly lower mean global DNA methylation than young individuals (Table 2). Larger differences were observed at specific loci. Old individuals had lower mean DNA methylation at five of nine loci (INS, KCNQ1OT1, and the three adjacent IGF2 loci; Table 2) and showed higher mean DNA methylation at three loci (LEP, ABCA1, and GNASAS). No difference was observed for CRH.

The interindividual variation in global DNA methylation expressed as the standard deviation (SD) was small in both age groups (SDyoung = 1.2% and SDold = 1.8%; Table 2). At specific loci, it ranged from small in both age groups at KCNQ1OT1 (SD = 2.3% in both age groups) to large in both age groups at ABCA1 (SDyoung = 7.8% and SDold = 9.6%; Table 2). With the exception of KCNQ1OT1, methylation variation was always larger in old individuals than in young individuals, irrespective of age-related differences in mean DNA methylation. The SD of global DNA methylation was 1.5-fold larger in old individuals (P = 2.3 × 10−5). At specific loci, the age-related difference ranged from 1.2-fold larger SD at ABCA1 (P = 0.010) to 1.6-fold larger SD at INS (P = 3.7 × 10−7; Table 2).

Within-pair discordance

The extent of within-pair methylation discordance was also compared between the young and old twins. Similar to the interindividual variation, a small within-pair discordance in global methylation was observed in both age groups. At specific loci, it ranged from small in both age groups at KCNQ1OT1 to large in both age groups at CRH. Furthermore, the absolute within-pair discordance in old MZ pairs was always greater than in young MZ pairs (Fig. 1A). Notwithstanding this overall increase, the old age group still contained pairs who had strikingly similar DNA methylation. With the exception of GNASAS, the SD of the within-pair differences, quantifying group discordance, was significantly higher in old as compared with young MZ pairs (Table 3). For global DNA methylation, methylation discordance in the old MZ pairs was almost double that of the young MZ pairs (P = 9.8 × 10−5). At specific loci, the increase in discordance ranged from 1.4-fold greater in old MZ pairs at KCNQ1OT1 (P = 0.005) to 2.7-fold greater at ABCA1 (P = 3.8 × 10−7).

DNA methylation across the complete adult lifespan

Changes in within-pair methylation discordance between different age categories

The timing of the occurrence of age-related changes in methylation discordance during adult life was investigated in 219 MZ pairs aged 18–89 years, including an additional 61 middle-aged MZ pairs (30–65 years old) and 25 old MZ pairs (> 65 years old; Table 5). In this extended set of MZ twins, global DNA methylation and methylation at five specific loci, representative of the nine loci studied in the young and old MZ pairs as described before, were measured (Table 1). The observed absolute

Fig. 1增加甲基化变异的年龄依赖性。绝对对对甲基化百分比差异的年龄依赖性图（图A）和特定位点的全球DNA甲基化和特定位点的甲基化百分比差异的年龄依赖性图（图B）。图C展示了19对老年MZ双胞胎（73-82岁）在10年随访后的数据。图中的条形图显示了四分位数范围，中心线表示中位数，而尖端表示5th（下尖端）和95th（上尖端）百分位数。
The increase in variation with age was observed, starting from early adulthood onward at IGF2 and CRH and from middle age onward at LEP. Age-related changes in discordance were less apparent at GNASAS and KCNQ1OT1 (Fig. 1B). Plotting the absolute within-pair methylation differences at individual CpG units against age yielded similar results (Figs S1–S6).

To quantify these observed changes, the proportional increase in discordance was also estimated per decade. For global DNA methylation, within-pair discordance was 9% greater each decade ($P = 3.4 \times 10^{-6}$; Table 4). The greatest increase in within-pair discordance was found at LEP with 16% greater discordance each decade ($P = 2.0 \times 10^{-10}$), and at IGF2 and CRH, within-pair discordance increased each decade with 11% ($P = 3.8 \times 10^{-09}$) and 8% ($P = 8.9 \times 10^{-06}$) respectively. At GNASAS, discordance did not change significantly with age. At KCNQ1OT1, although the discordance was small at all ages, it did increase by 11% each decade ($P = 0.002$; Table 4). These observed relative increases in discordance were confirmed with absolute differences in the amount of discordance when testing the homogeneity of variance in discordance across the age groups at individual CpG units (Table S7).

Dutch and Danish MZ pairs were investigated in this study. The observation that the increase in within-pair discordance was not exclusive to the old age group (predominantly Danish twins) but was already apparent at younger age (Dutch twins) indicated that geographic origin of the MZ pairs did not contribute to our findings. To further exclude the influence of origin, we tested whether age-related changes in methylation variation or discordance were different between old Dutch ($n = 25$ pairs) and Danish ($n = 67$ pairs) twins. No significant influence of country on age-related changes was observed for either variation or discordance (Table S2).

### Longitudinal changes in DNA methylation in old age

Interindividual and within-pair epigenetic variations, global and at the same 5 loci, were also investigated in 19 elderly twin pairs during 10 years of follow-up (DNA samples obtained in 1997 and 2007). Global and locus-specific interindividual methylation variation was modestly larger after 10-year follow-up, except at CRH (Table S5). Changes in within-pair methylation discordance showed a similar pattern as observed in comparing changes from young to old adults (Fig. 1: compare C with A and B). Global discordance and that at three loci (IGF2DMR, LEP, and CRH) had increased during the follow-up period, whereas no change was observed at the remaining two loci (KCNQ1OT1 and GNASAS).

### Familial and unique environmental factors

The study of MZ twin pairs enables separation of the effects of familial (i.e., genetic and common environment) and unique (individual) environment on the accumulation of DNA methylation differences with age. For global methylation, the total variation was relatively small and mainly attributable to unique environment. The increase in variation with age...
was limited but significant (\( P = 0.004 \)) and mostly attributable to unique environment (\( P = 0.003; \) Fig. 2, top left graph; Table S6). The total variation increased significantly with age at all loci in line with the previous analyses (Table S6). This increase could be mainly attributed to unique environmental factors except for the age-related increase in variation at \( CRH \) methylation which had a familial component (\( P = 0.007 \)).

**Discussion**

In this study, we report sustained age-related increases in variation of DNA methylation, in an analysis of 460 individuals, comprising 230 MZ pairs, aged from 18 to 89 years. Previously, this question was investigated using cross-sectional and longitudinal study designs on smaller sample sizes with narrower age ranges (Fraga et al., 2005; Feinberg et al., 2010; Gronniger et al., 2010; Talens et al., 2010). Our study extends their findings over the full adult lifespan, supporting the notion that a gradual accumulation of epigenetic changes, globally and at imprinted and non-imprinted loci, occurs up to very old ages. How such changes affect gene expression remains unclear, although some evidence suggests that small differences in DNA methylation may cause an amplified effect on gene expression (Lillycrop et al., 2008). The increase in epigenetic variation was mainly attributable to unique individual factors that cover both stochastic processes and environmental exposures, between which the design of our study cannot distinguish. This may lead to age-related epigenetic dysregulation and may contribute to the age dependency of common diseases (Jaenisch & Bird, 2003; Björnsson et al., 2004). However, studies that can appropriately address the latter hypothesis will be complex in their design and execution because of the relatively small effect sizes involved and the tissue- and cell-specific nature of age-related changes (Heijmans & Mill, 2012).

We measured LINE1 methylation to assess global DNA methylation (Wang et al., 2010) and found that the variation in global DNA methylation, both interindividual and within-pair, was small at all ages but increased proportionally with age, in accordance with a longitudinal study over 10 years (Björnsson et al., 2008). The small amount of global variation observed may relate to the fact that global DNA methylation assays measure methylation at a multitude of similar loci distributed throughout the genome (Bollati et al., 2009; Wang et al., 2010), while the introduction of stochastic changes occurs at individual loci. We observed the most prominent age-related changes in variation at specific candidate loci for common age-related diseases, such as \( IGF2 \), \( LEP \), and \( CRH \), of which the expression was shown to be influenced by its DNA methylation (Melzner et al., 2002; Cui et al., 2003; McGill et al., 2006).

We observed a substantial difference between the loci in their vulnerability to epigenetic drift, which was consistently found in our various analyses (interindividual variation, within-pair discordance, young versus old individuals, the adult lifespan, or a longitudinal analysis in old subjects). Of interest, the greatest age-related changes were observed for nonimprinted loci, whereas imprinted loci appeared more stable.

MZ twin pairs share characteristics such as age, sex, genotype, and their developmental and childhood environment (e.g., upbringing/education). They may acquire more unique characteristics as they grow older, because different choices on, for instance, lifestyle and occupation can increasingly change their living environments. The shared characteristics, namely their genotype and shared environment, and their individual characteristics, commonly named the unique environment, may both contribute to epigenetic variation (Martin, 2005; Bell & Spector, 2011). We used the MZ twin study design to investigate how much of the age-related increase in variation is contributed by the familial factors and by the unique individual environment (Purcell, 2002; Bell & Spector, 2011). We
observed that most of the variation in young adults could be attributed to the individual environment, indicating that DNA methylation is at least partly independent of familial (i.e., genetic) factors. Interestingly, studies on neonate and infant MZ pairs indicated that such differences are already present and indeed increase at a very young age (Ollikainen et al., 2010; Wong et al., 2010). At most loci, we found that the age-related changes in variation were also mostly attributable to the unique individual environment, supporting the idea that age-related changes in DNA methylation may be mostly independent from familial factors (Jaenisch & Bird, 2003; Björnsson et al., 2004; Martin, 2009). However, at CRH, the increase in variation was mostly attributed to familial factors. Residual batch effects seem an unlikely explanation for this observation, considering that the design of this study involved a batch allocation scheme that took age and sex into account and the statistical models contained a factorial variable to adjust for its potential influence. A previous study reported familial clustering of variation over time in global DNA methylation using the LUMA assay (Björnsson et al., 2008). As we studied MZ twins only, we cannot further distinguish whether this familial component is related to genetic or shared environmental factors, both of which may influence the susceptibility to stochastic or environmentally driven changes in DNA methylation (Sandovic et al., 2003).

In this study, we observed that differences in mean methylation between the young and the old age groups were relatively small or even absent, while increases in variation were generally more substantial. This finding indicates that epigenetic changes accumulating with age are generally nondirectional or are the outcome of many smaller directed changes with, in part, opposite direction. Changes in DNA methylation can be stochastic or environmentally driven; the relative contribution of each source of variation cannot be investigated in our study. Stochastic epigenetic changes can occur without any environmental influence and may be related to imperfect DNA methylation maintenance mechanisms (Petronis, 2006). We observed that the age-related increase in variation of DNA methylation was gradual from early adulthood to old age, which is compatible with stochastic effects (Björnsson et al., 2004). Environmentally driven epigenetic changes may occur as a consequence of environmental exposures related to, for instance, lifestyle and occupation (Bollati et al., 2007; Gronniger et al., 2010; Breitling et al., 2011). It is even conceivable that stochastic epigenetic changes occur more often under certain environmental conditions, parallel to stochastic genetic mutations that occur after exposure to high UV irradiation.

The power of cross-sectional studies in MZ twins is that large age ranges can be studied in contrast to what is practically possible in longitudinal studies on unrelated individuals. We investigated changes in epigenetic variation, in terms of both interindividual variation and within-pair difference, over a large age range. We observed similar increases in either measure of epigenetic variation throughout the adult lifespan. These results are in line with longitudinal analyses over relatively short time spans in old age, as we report here, middle age (Feinberg et al., 2010; Talens et al., 2010), and childhood (Wong et al., 2010). In view of the consistency of these findings, it is unlikely that generation effects significantly contributed to our findings. Importantly, we were also able to exclude age-related changes in cellular heterogeneity of whole blood as an explanation for our observations, which was previously proposed as a major concern for the interpretation of such studies (Martin, 2005). Whether increased methylation variation in blood has any biological (phenotypic) relevance is an important and as yet unresolved question, although it is likely that other tissues than blood are similarly affected by epigenetic drift (Ronn et al., 2008; Gronniger et al., 2010; Wong et al., 2010). In general, tissues with a high rate of cell division may display more age-related epigenetic variation through stochastic errors in maintaining and transmitting epigenetic information than tissues with lower rates of cell division (Thompson et al., 2010).

In this study, we investigated DNA methylation of MZ twin pairs with ages distributed across the full adult lifespan. In the first phase of the study, we explored differences by comparing young adult twins (18–30 years) with old twins (> 74 years) to generate sufficient contrast between groups. Such age groups at either extreme of the adult lifespan could not be selected from a single twin register. This required a careful consideration of potential biases created by selecting young twins from the Netherlands and old twins from Denmark and additional measures to confirm the validity of our findings. Genetic differences between the populations were unlikely to play a role, because a genome-wide analysis of SNPs of Northern European countries reported a similar structure of genetic variation in the two countries (McEvoy et al., 2009). Further, similar procedures were used for drawing blood (Christensen et al., 2008; Willemsen et al., 2010), DNA was extracted using standard protocols, and there was no indication for differences in DNA quality [including OD 260/280 measurements, bisulfite (BS) conversion rate and success rate of DNA methylation assays]. Moreover, if DNA quality was different between the populations, one would expect a similar systematic effect on all assays, which could be taken into account in our statistical analysis. In contrast, the loci we studied showed a substantial difference in the degree to which the variation in DNA methylation was higher in old twins, which was absent for KCNV10T1. More importantly, we experimentally validated the finding from the first phase for six loci. In this second phase, we compared the old Danish twins with a subset of Dutch twins specifically selected for a maximum age overlap [within the limitations of the availability of old twins in the Netherlands twin register (NTR)]. We found no indication for DNA methylation differences between Dutch and Danish twins with a similar old age. Furthermore, the locus-specific associations of DNA methylation variation with age originally observed in the young–old comparison were confirmed both in an investigation of intermediate age ranges selected from the NTR and in a longitudinal investigation of old Danish twins. Taken together, differences in geographic or technical variability between populations are unlikely explanations for our observations in phase one of our study, and the second phase yielded further evidence for the occurrence of sustained epigenetic changes during the adult lifespan.

In this study, we demonstrate that epigenetic variation in the population, used as a proxy for stochastic and environmentally driven epigenetic changes in individuals, increases gradually with age up to old age. The rate at which changes are introduced differs between loci and can be considerable at loci regulating transcription of nearby genes. The observed increase was mostly driven by the unique environment. Our results have practical implications for study design in epigenetic studies investigating populations with a large age distribution or a long follow-up time (Foley et al., 2009; Talens et al., 2010). Future research should aim to investigate the relative contribution of stochastic and environmental factors to age-related epigenetic changes and the consequences of these changes for the development of common age-related diseases.

**Experimental procedures**

**Study population**

The samples in this study are taken from Longitudinal Study of Aging Danish Twins (LSADT) of the Danish Twin Registry (DTR; McGue & Christensen, 2007) and from the Biobank project of the NTR (Willemsen et al., 2010). In the LSADT study, DNA was extracted using the salting out method, and in the Biobank project, QIAamp DNA Blood Maxi (Qiagen,
Düsseldorf, Germany) was used. DNA from both sources was of high quality (260/280 BioDENTANK = 1.80; 260/280 LSADT = 1.90).

Selection from the Danish Twin Registry (DTR)
The LSADT study, based on the DTR, is a cohort sequential study of elderly Danish twins. LSADT began in 1995 with an assessment of all members of like-sex twin pairs born in Denmark before 1920. The surviving members were followed up every 2 years, and additional cohorts were added at the 1997, 1999, and 2001 assessments and subsequently followed at 2-year intervals. During a home visit in 1997, blood was drawn from 689 individuals, from which DNA was isolated (Skytte et al., 2006). The LSADT project has been approved by the Danish National Committee on Biomedical Research Ethics (journal VF 20040241). Details on design and data collection were described previously (Christensen et al., 2008).

This study focuses on the monozygotic twin pairs (MZ pairs) of whom DNA was available from the 1997 assessment, (73 years or older; n = 108 pairs). To investigate differences in epigenetic variation between young and old MZ pairs, all 36 male MZ pairs and 37 randomly selected female MZ pairs formed a study population named ‘old Danish twins’ (Table 5). For two male MZ pairs and four female MZ pairs, there was insufficient DNA of both co-twins. These MZ pairs were excluded, and the remaining 67 MZ pairs were investigated. For 19 of the LSADT MZ pairs (eight male pairs), a second DNA sample was available from a 10-year follow-up in 2007 for both co-twins. Longitudinal epigenetic changes in the elderly were investigated in these MZ pairs, who were named ‘follow-up Danish twins’ (Table 5).

Selection from the Netherlands Twin Register (NTR)
In 2004, the NTR started a large-scale biological sample collection in twin families to create a resource for genetic studies on health, lifestyle, and personality. Between January 2004 and July 2008, adult participants of the NTR (18 years and above) were invited to the project. During a home visit, fasting blood was drawn, from which DNA was extracted and a hematological profile was obtained, consisting of percentages and numbers of neutrophils, lymphocytes, monocytes, eosinophils, and basophils. The study protocol was approved by Central Ethics Committee on Research Involving Human Subjects of the VU University Medical Center, Amsterdam, an Institutional Review Board certified by the US Office of Human Research Protections (IRB number IRB-2991 under Federal-wide Assurance-3703; IRB-institute codes, NTR 03-180). Details on design, biological sampling, and data collection were described previously (Willemsen et al., 2010).

To investigate differences in epigenetic variation between young and old MZ pairs, 37 MZ pairs of each sex were randomly selected from all NTR MZ pairs who were under 30 years old at sampling (n = 98 pairs, 44 male pairs). For three male and five female MZ pairs, there was insufficient DNA of both co-twins. These MZ pairs were excluded, and the remaining 66 MZ pairs were named ‘young Dutch twins’ (Table 5). To investigate differences in epigenetic discordance over the full adult lifespan, 37 MZ pairs were selected from all NTR MZ pairs between 30 and 50 years of age (135 pairs, 34 male pairs) using a block random selection procedure to guarantee an even distribution over the age range. They were combined with all NTR MZ pairs who were above 50 years of age (49 pairs, 16 male pairs). The MZ pairs between 30 and 65 years of age were named ‘middle-aged Dutch twins’ (n = 61; 15 male pairs), and the MZ pairs above 65 years of age were named ‘old Dutch twins’ (n = 25; eight male pairs; Table 5).

DNA methylation

Assays and measurement
DNA methylation was measured using a quantitatively accurate mass spectrometry-based method (Epityper version 1.05, Sequenom, San Diego, CA, USA; Coolen et al., 2007; Ehrich et al., 2008). A total of 10 DNA methylation assays were measured in this study, the LINE1 assay for global DNA methylation (Wang et al., 2010) and nine assays for DNA methylation at seven specific genomic loci [IGF2 (3 assays), LEP, CRH, ABCA1, IN5, KCNQ1OT1, and GNASAS; Table 1]. Two novel assays were designed to assess methylation of the CpG sites directly telomeric, named IGF2_qter and centromeric, named IGF2_qter, of the assay at the IGF2 locus’ DMR (Heijmans et al., 2007), named IGF2DMR for clarity. The primers of each assay were designed to create a PCR bias for completely BS-converted DNA (Li & Dahiya, 2002). More details on the design, features, and measurement of the other eight methylation assays were described in detail previously (Heijmans et al., 2007; Talens et al., 2010; Wang et al., 2010). Briefly, BS conversion of 0.5 μg of genomic DNA using the EZ 96-DNA methylation kit (Zymo Research, Orange, CA, USA) was followed by PCR amplification (primers are given in Table S1A), fragmentation after reverse transcription, and analysis on a mass spectrometer. Fragments that contain one or more CpG sites are called CpG units.

Randomization and quality control
All methylation assays were measured in triplicate on the same BS-converted DNA sample. DNA samples of both co-twins of an MZ pair were always allocated to the same batch for BS conversion (on 96-well plate) and PCR amplification (384-well plate, 3 x 124 DNA samples). Each

batch contained equal proportions of the age groups measured and the sexes, and each PCR batch contained equal proportions of the BS conversion batches. There were two phases of methylation measurement in this study. First, all ten methylation assays were measured in the young Dutch and the old Danish twins, who were randomly divided over the measurement batches. The ten assays contained a total of 74 measurable CpG units, over which 102 CpG sites were distributed (Table 1). After quality control (Talens et al., 2010), 65 CpG units, containing 93 CpG sites, remained, with a mean call rate of 96.5%.

In the second phase, six methylation assays representing observations on the ten assays were measured in the middle-aged and old Dutch twins, who were randomly divided over the measurement batches, and in the follow-up Danish twins, who were all allocated to a single measurement batch. The six loci contained a total of 47 CpG units, over which 66 CpG sites were distributed. After quality control, 42 CpG units, containing 61 CpG sites, remained both for the Dutch twins (average call rate = 96.4%) and for the follow-up Danish twins (average call rate = 95.7%). These CpG units were the same that passed quality control in the first phase. Table S1B gives the CpG units and CpG sites that passed quality control of each assay and the call rates per assay in both phases.

Bisulfite conversion was assessed using the MassArray R package (Thompson et al., 2009), which identifies CpG-less fragments containing a TpG and a cytosine on the assay’s original genomic sequence. It analyzes the mass spectra, treating these fragments as hypothetical CpG sites, because incomplete BS conversion would result in the same mass shift as Cytosine methylation at a CpG site. For both Danish and Dutch twins, this analysis qualified BS conversion as complete within the technical limitation of the method.

Statistical analysis

Definitions
Methylation variation: the standard deviation of the mean (SD) of the interindividual differences within a group.
Within-pair methylation difference: the within-pair DNA methylation difference at each CpG site, with DNA methylation of co-twin 1 as the reference: difference = Twin1 – Twin2.
Methylation discordance: the range of the within-pair differences in a group. To quantify age-related changes in discordance, the SD of the within-pair differences in a group is used. In figures, the absolute within-pair differences (absolute discordance) are used.
Days: a continuous variable for the time between the drawing of blood from each co-twin of a twin pair computed in days, with co-twin 1 as the reference.
Batch: a categorical variable with a distinct designation for each combination of PCR and BS batch.

Linear mixed models, description of basic models
Linear mixed models were used to test for age-related changes in DNA methylation of the assays, its variation, and its discordance, as previously described (Tobi et al., 2009; Talens et al., 2010). More details on the linear mixed model are given in the Data S1 (Supporting information).

In all the linear mixed models used for testing age-related changes in interindividual methylation variation, DNA methylation was entered as a dependent variable. Individual was the subject variable. Necessary adjustments were made by entering age, sex, twin designation (T1 or T2, to account for nonindependence), batch, and CpG unit as fixed effects. In all the linear mixed models used for testing age-related changes in within-pair methylation discordance, the within-pair difference was entered as a dependent variable. Family was the subject variable. Necessary adjustments were made by entering age_{Twin1}, days, sex, batch, and CpG unit as fixed effects. Both basic models were adapted to suit each specific test as described below.

Adaptation of basic models for each specific test
DNA methylation, methylation variation, and methylation discordance were compared between young Dutch (n = 66 pairs) and old Danish twins (n = 67 pairs). Age group (young or old) was added to the models as a random effect to test for differences in variation or discordance and as an extra fixed effect, replacing age, to estimate adjusted group mean methylation or mean within-pair difference and its SD [using the standard error (SE) of the mean] and test for group differences.

Changes in methylation discordance over the full adult lifespan were tested in all Dutch and the old Danish twins (n = 219 pairs), and age was entered as a random effect.

Longitudinal methylation variation was investigated in the follow-up Danish twins (n = 19 pairs), and the model was adapted as follows: DNA sample (i.e., individual per year of sampling) was the subject variable.
Year of sampling (1997 or 2007) was entered as an extra random effect and as an extra fixed effect. Adjustment for age was made using age at first sampling, and no adjustment for batch was required.

Adjusted mean DNA methylation, the differences in means, interindividual variation, and within-pair discordance are all expressed as percentage DNA methylation. The fold change in methylation variation and discordance between groups is expressed as a proportion by dividing the SD in the older group with the SD in the younger group (SD_{older}/SD_{younger}). The change in discordance over the adult lifespan is expressed as the proportional increase each decade as percentage of the discordance of the previous decade. Significance of the age-related changes in variation or discordance was tested with a one-sided Z-test applied on the random effect estimate of age group, age, or sampling time divided by its SE, which adds up to a Wald test.

Adaptation of basic models for subsidiary tests
To test whether age effects were similar between Dutch and Danish individuals, methylation variation and discordance were compared between old Dutch twins (n = 25 pairs) and old Danish twins (n = 67 pairs). Age was entered as an extra random effect. An interaction term age*country was entered as an extra fixed effect, insignificance of which would establish that Dutch and Danes represent the same population.

Nested linear mixed models were used to investigate confounding by leukocyte population heterogeneity, approximated by percentage neutrophils, as recently described (Talens et al., 2010). Confounding of methylation variation and discordance was tested on the young Dutch twins (n = 66 pairs). Confounding of age-related changes was tested on all Dutch twins (n = 152 pairs). The basic models are as described above, with age also entered as a random effect when testing age-related changes. Nested models had percentage neutrophils for testing its influence on methylation variation and the within-pair difference in percentage neutrophils (Twin 1 – Twin 2) for testing its influence on methylation discordance, added to their corresponding basic model as an extra fixed effect. The amount of confounding is determined by the change in residual variance, or the change in the random effect estimate of age, in the nested model with respect to the basic, as described previously (Talens et al., 2010).
Variance component models for twin analysis

In this study, interindividual methylation variation and within-pair methylation discordance have been investigated separately. In the statistical models commonly used in twin research, both aspects of variation can also be investigated simultaneously, thus correcting each component for the other. The classical twin model for MZ twins (Purcell, 2002) postulates that the methylation values \( y \) at a given locus for co-twins 1 and 2 of twin pair \( i \) are defined by an overall mean \( \mu \) that may depend on age, sex, batch, CpG unit, by a random twin-pair effect \( b_1 \), the familial environment, which stands for the shared factors of the twin pair, including common environment and genotype, and by a residual error \( e_1 \), the individual environment which stands for the factors that are unique to each co-twin (in formula: \( y_i = \mu + b_1 + e_1 \)). However, this classical twin model is not able to capture that the methylation variance increases with age. We therefore used the following extension of the classical twin model to allow for such age variation: \( y_i = \mu + b_1 + e_1 + \alpha_i \cdot \beta_1 \cdot y_i + \alpha_i \cdot \beta_2 \cdot \gamma_i \), with \( \mu, \beta_1, \beta_2 \), and \( e_1 \) as before and \( \alpha_1 \) and \( \gamma_1 \) quantifying shared (familial) and unique (individual) age effects independently from each other and from \( b_1 \) and \( e_1 \). More details on these MZ twin variance component models (Purcell, 2002) are given in the Data S1 (Supporting information).

In the linear mixed models used to test the individual and familial components of variation in DNA methylation over the adult age range \( n = 219 \) pairs), DNA methylation was entered as a dependent variable. Individual and family were both subject variables. Age was entered as a random effect around family (with the intercept) and as a random effect around individual, thereby adjusting each variance component for the other. For necessary adjustments, age, sex, batch, and CpG unit were entered as fixed effects. Significance of the age-related increases in total, familial, and individual variation was tested with a one-sided Z-test applied on the random effect estimates of age.

The square root of the resulting random effect estimates represents an estimation of the SD, which, expressed as percentage DNA methylation, is easier to interpret. The total of all variation (residual variance, intercept, and familial and individual age-related estimate) and the individual variation (residual variance and individual age-related estimate) was plotted against age to visualize the familial and individual age-related increase in variation, because total variance minus individual variance represents the familial variance.
